NG Dipole Renders

The dipole work of the October discovery pass, drawn from the committed summaries on codex/ng-shadow-discovery-20261108: the frozen roll-20 detector on four sessions (October 2, 3, 17 and 18, 2023), its clocks, its states, and what they do and do not carry. Every figure has its numbers in a table below it. Hover a mark for its value. No trade cost enters anything shown.

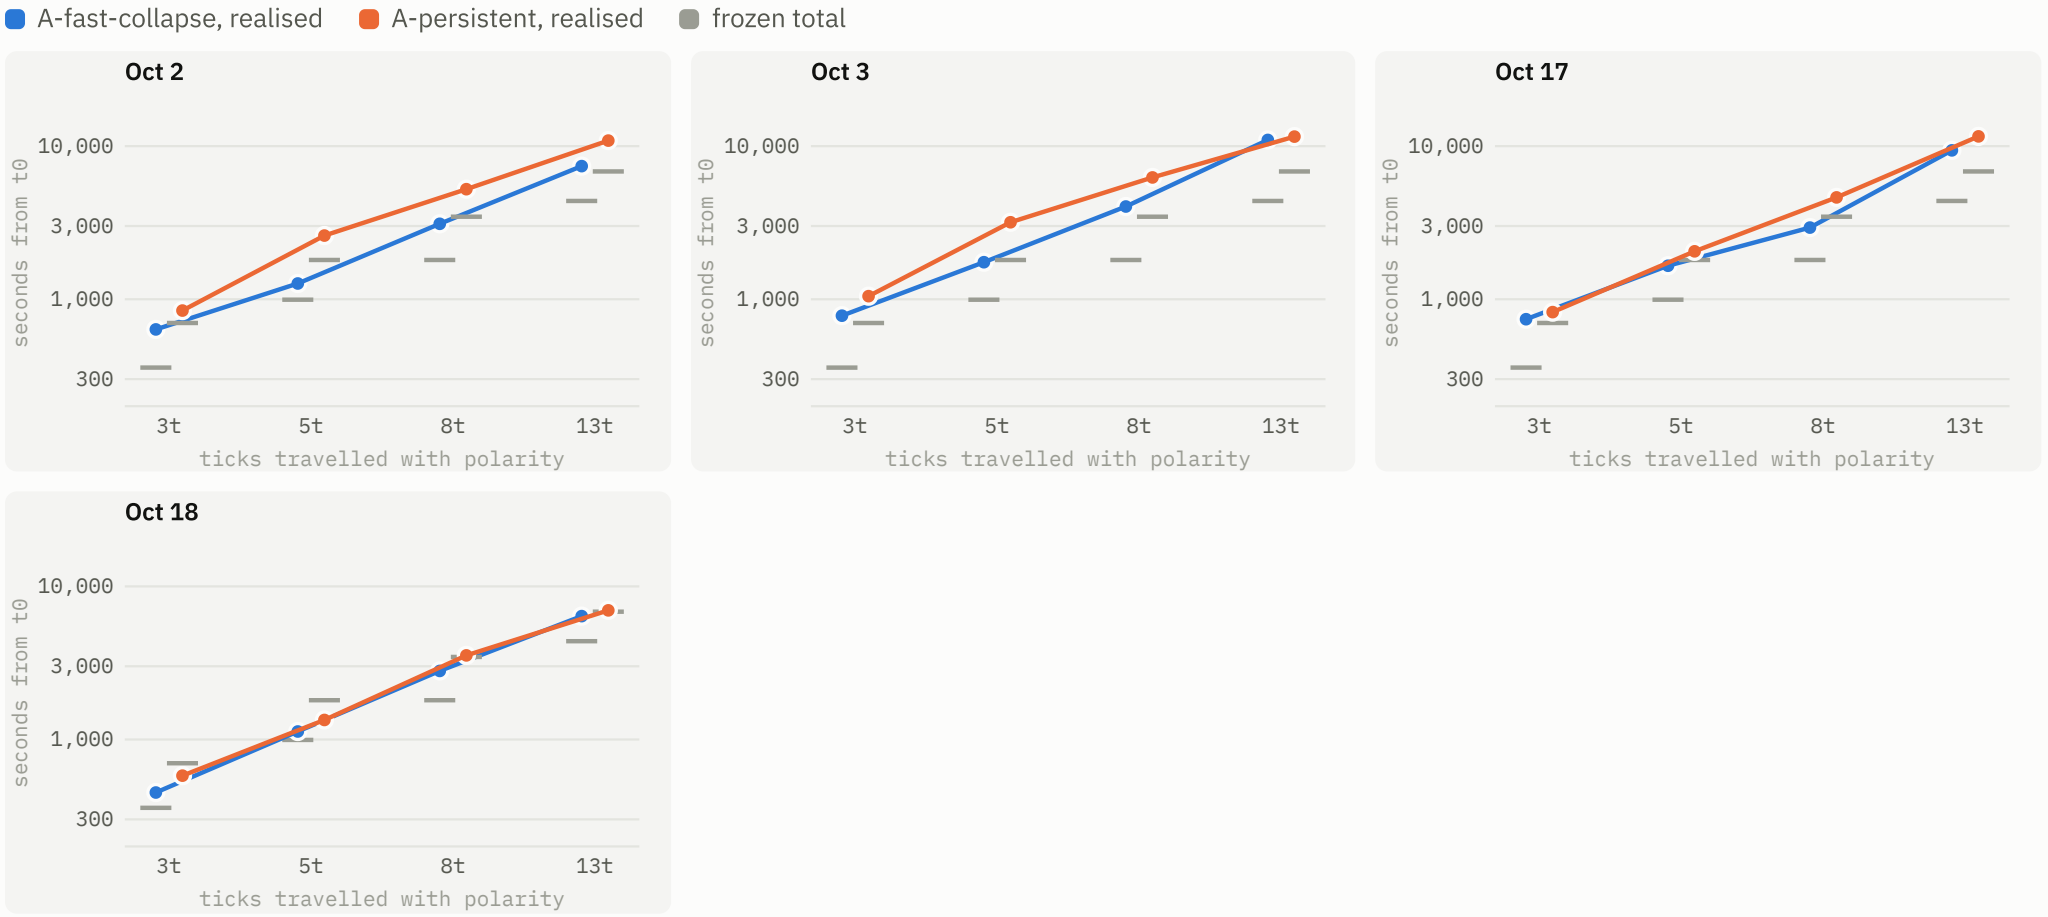

1. Three clocks of the frozen dipole detector

Runway (t0 to onset) and confirmation sit at 31 to 38 s median on every session; the archived recognition arrives at 51 to 52 s. Roughly six in ten bursts are over before they are knowable.

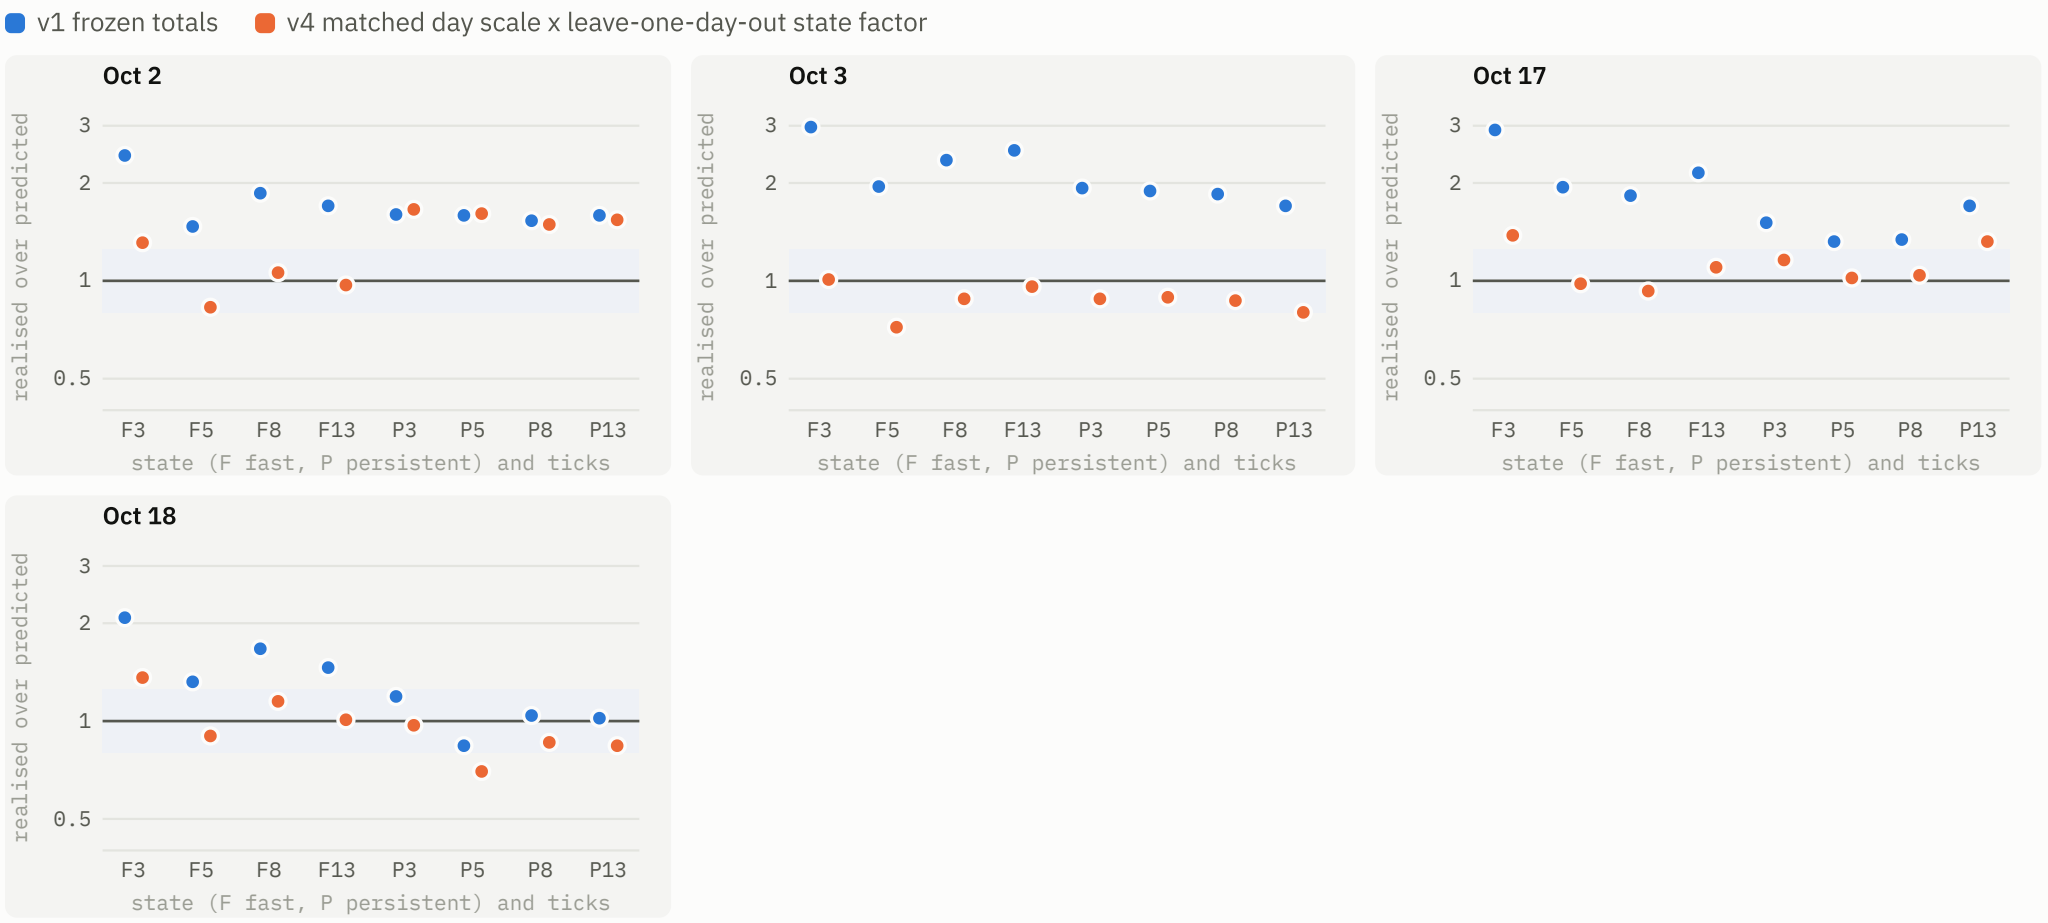

2. The frozen duration math on four sessions

Persistent beats fast-collapse at every scale on every day (16 of 16). The frozen totals (gray dashes) match the persistent state on October 18 only; elsewhere both states run long.

3. The delivered clock: frozen (v1) against day-scaled with state factor (v4)

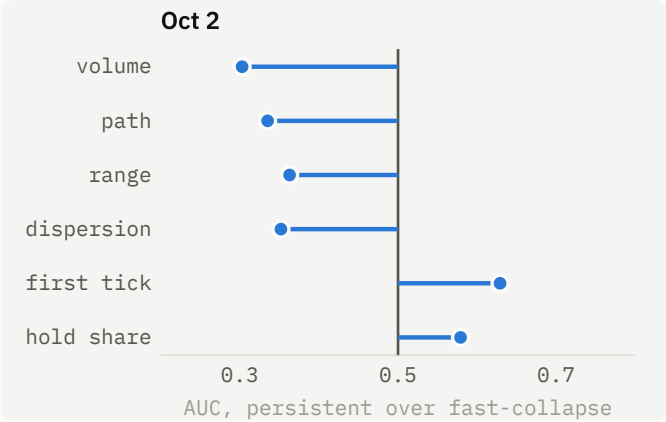

The shaded band is within 20 percent of calibrated. v1 lands 4 of 32 cells in it; v4 lands 22 of 32 with a reach-within-prediction share of 0.48 against 0.50 ideal.

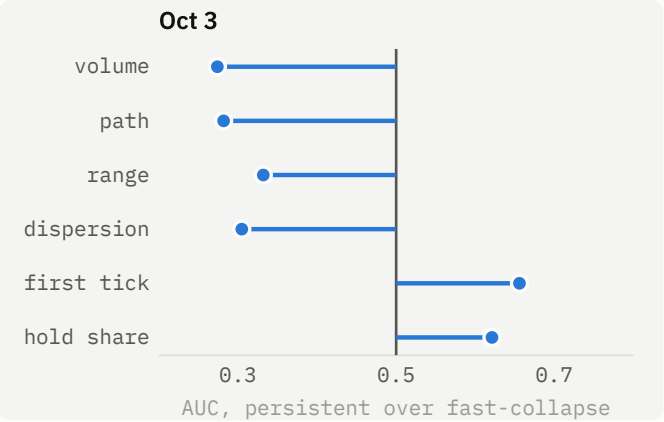

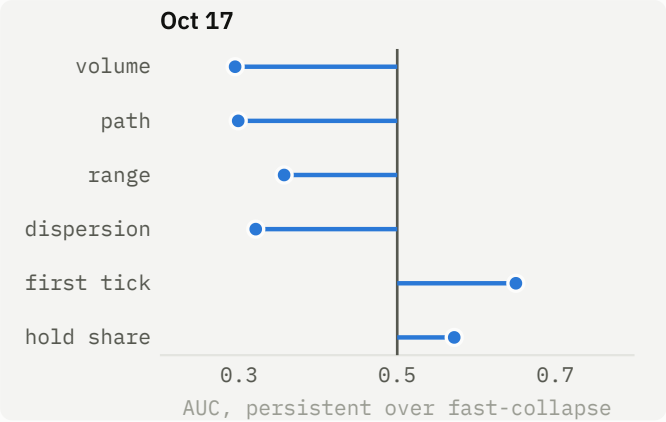

Ratios above 1 mean the clock said too soon; v4's factors for a day never use that day.

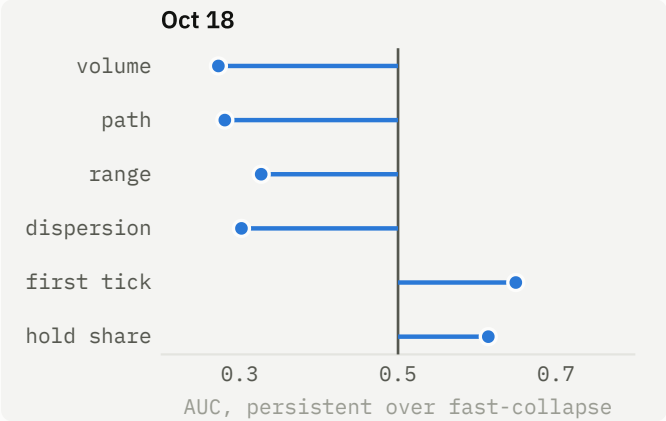

4. What the state carries besides direction (600 s after the +60 anchor)

The persistent state marks a quieter aftermath on every session: less volume, path and range, a slower first tick and a longer hold. Most of it is pre-birth activity carried forward.

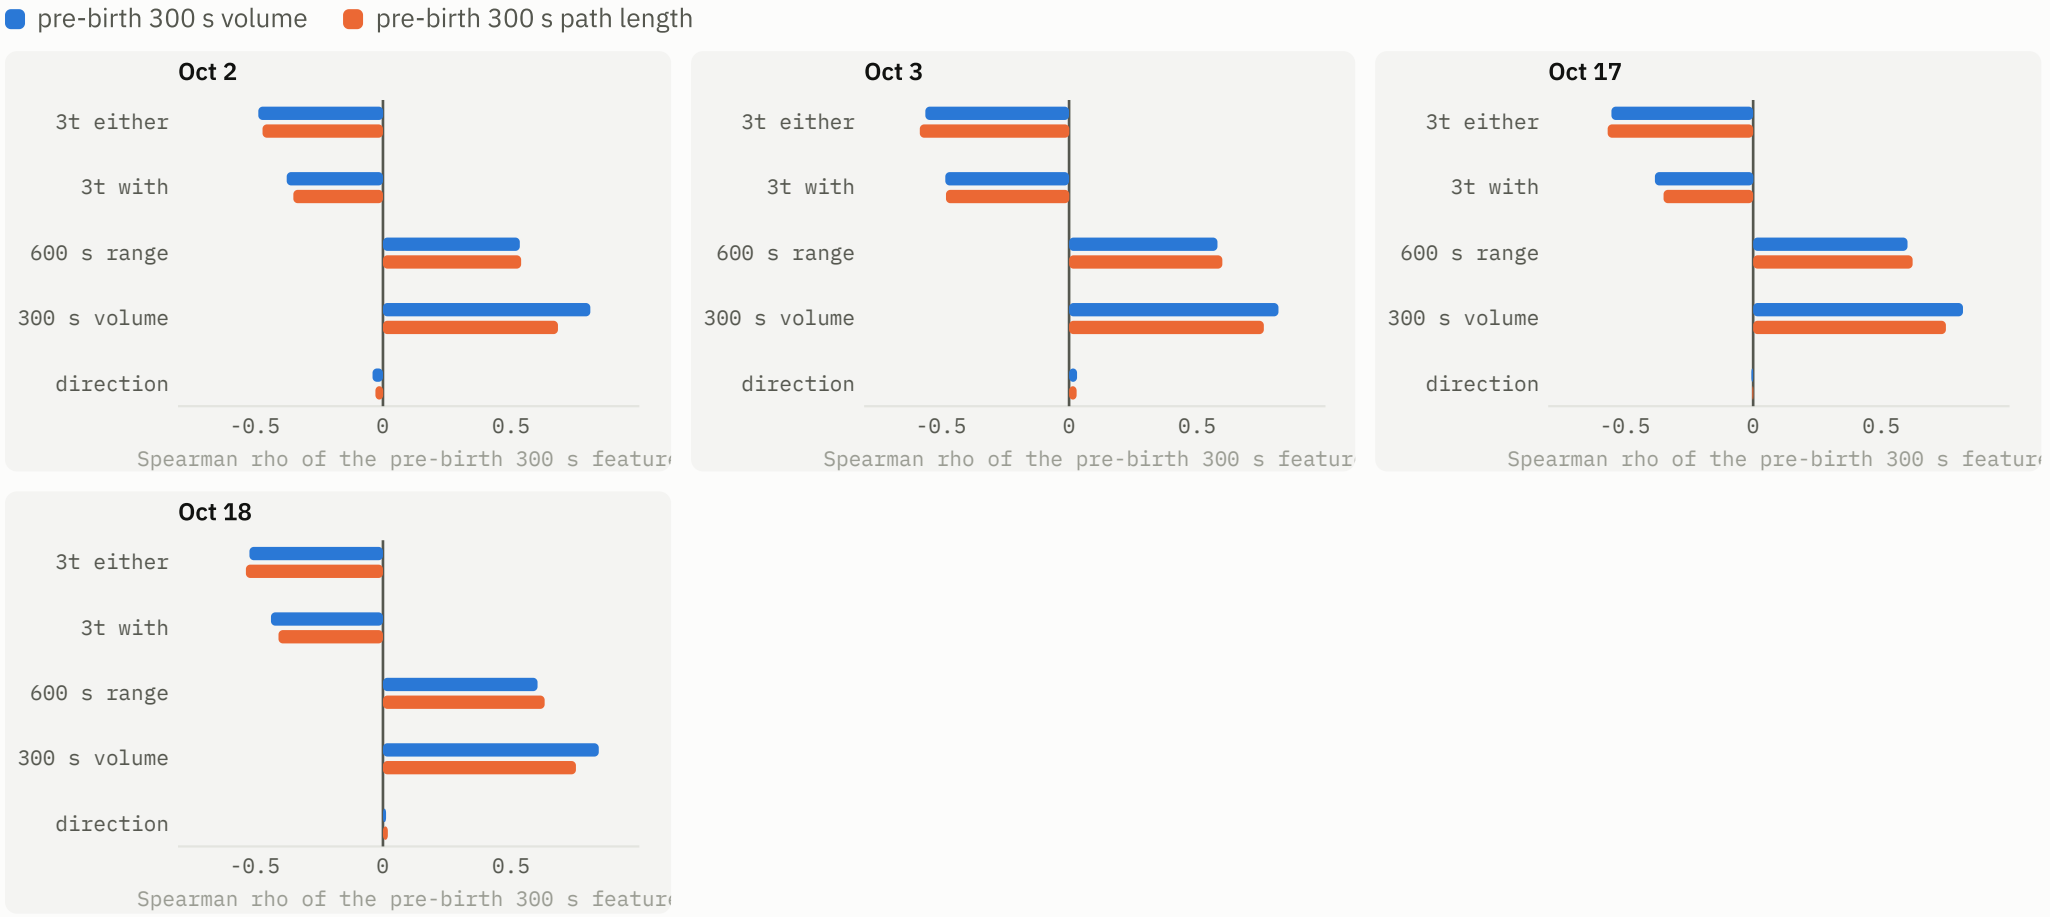

5. Pre-birth activity predicts the clocks, not the direction

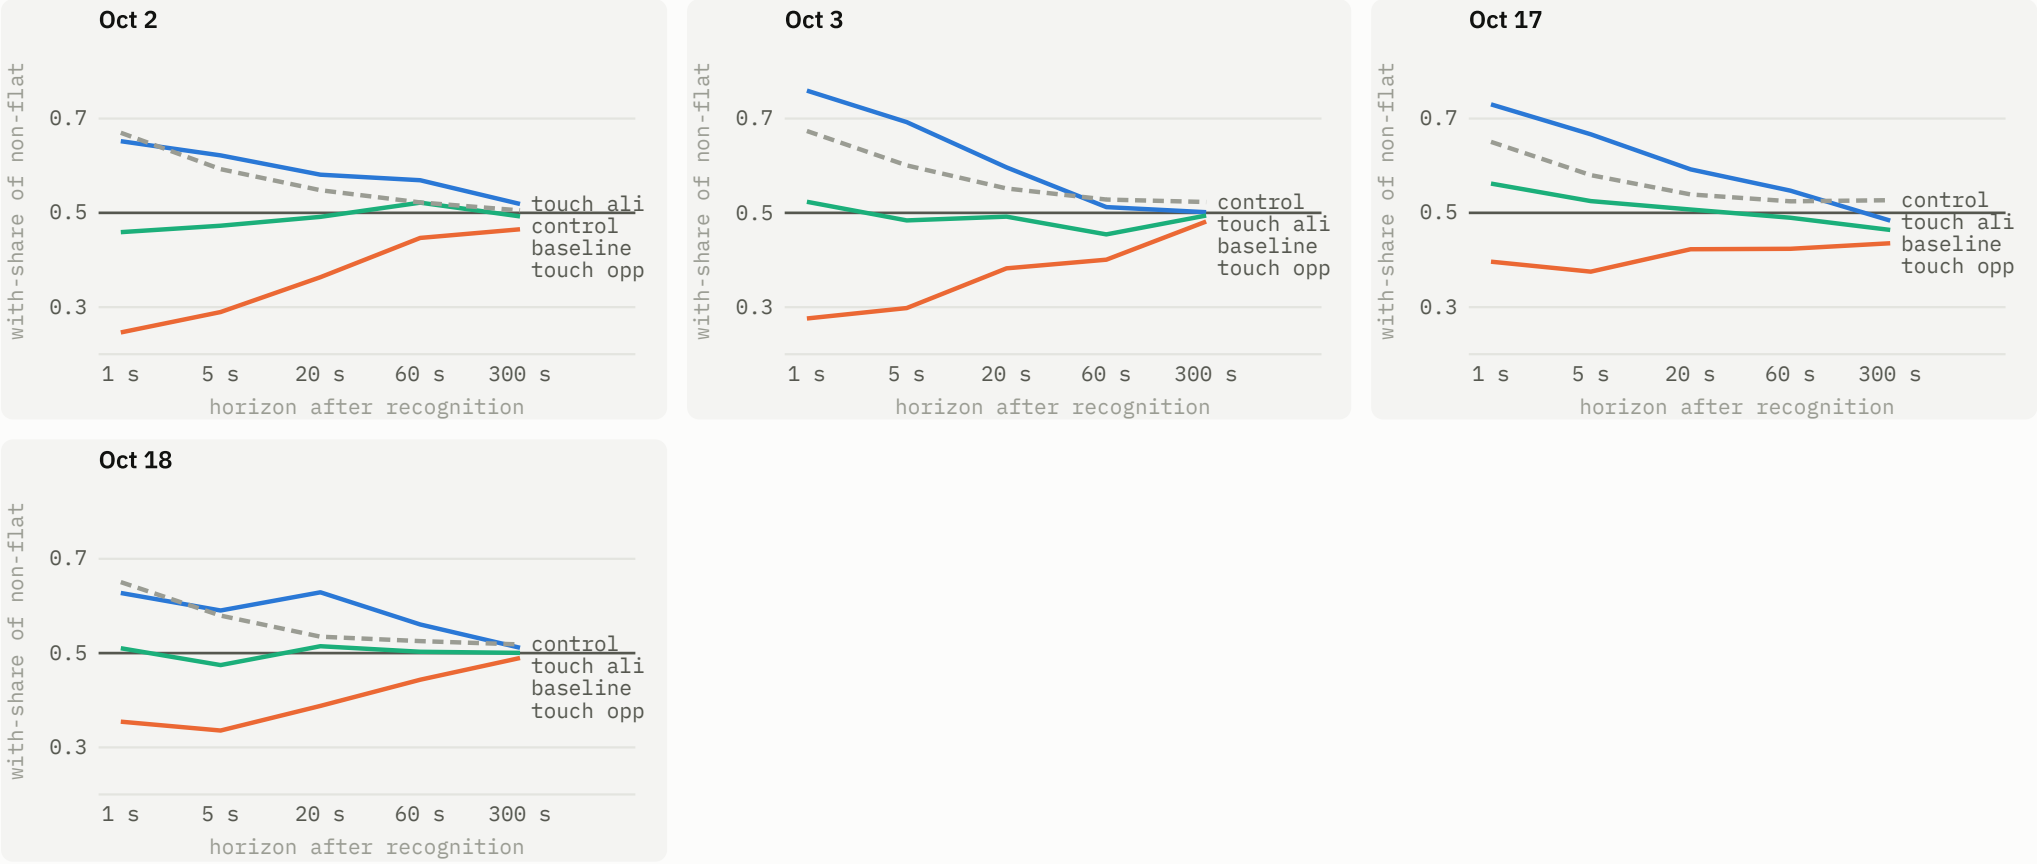

The 300 s volume and path before t0 correlate about minus 0.5 with the time to 3 ticks and about plus 0.6 with the 600 s range on all four sessions, and 0.0 with the oriented 300 s change.

6. After the actual archived recognition: direction, and the touch read against its control

Birth polarity carries nothing at any horizon on any session. The heavier touch side wins the next few ticks and decays to the all-seconds control by 300 s; the control has no dipole in it.

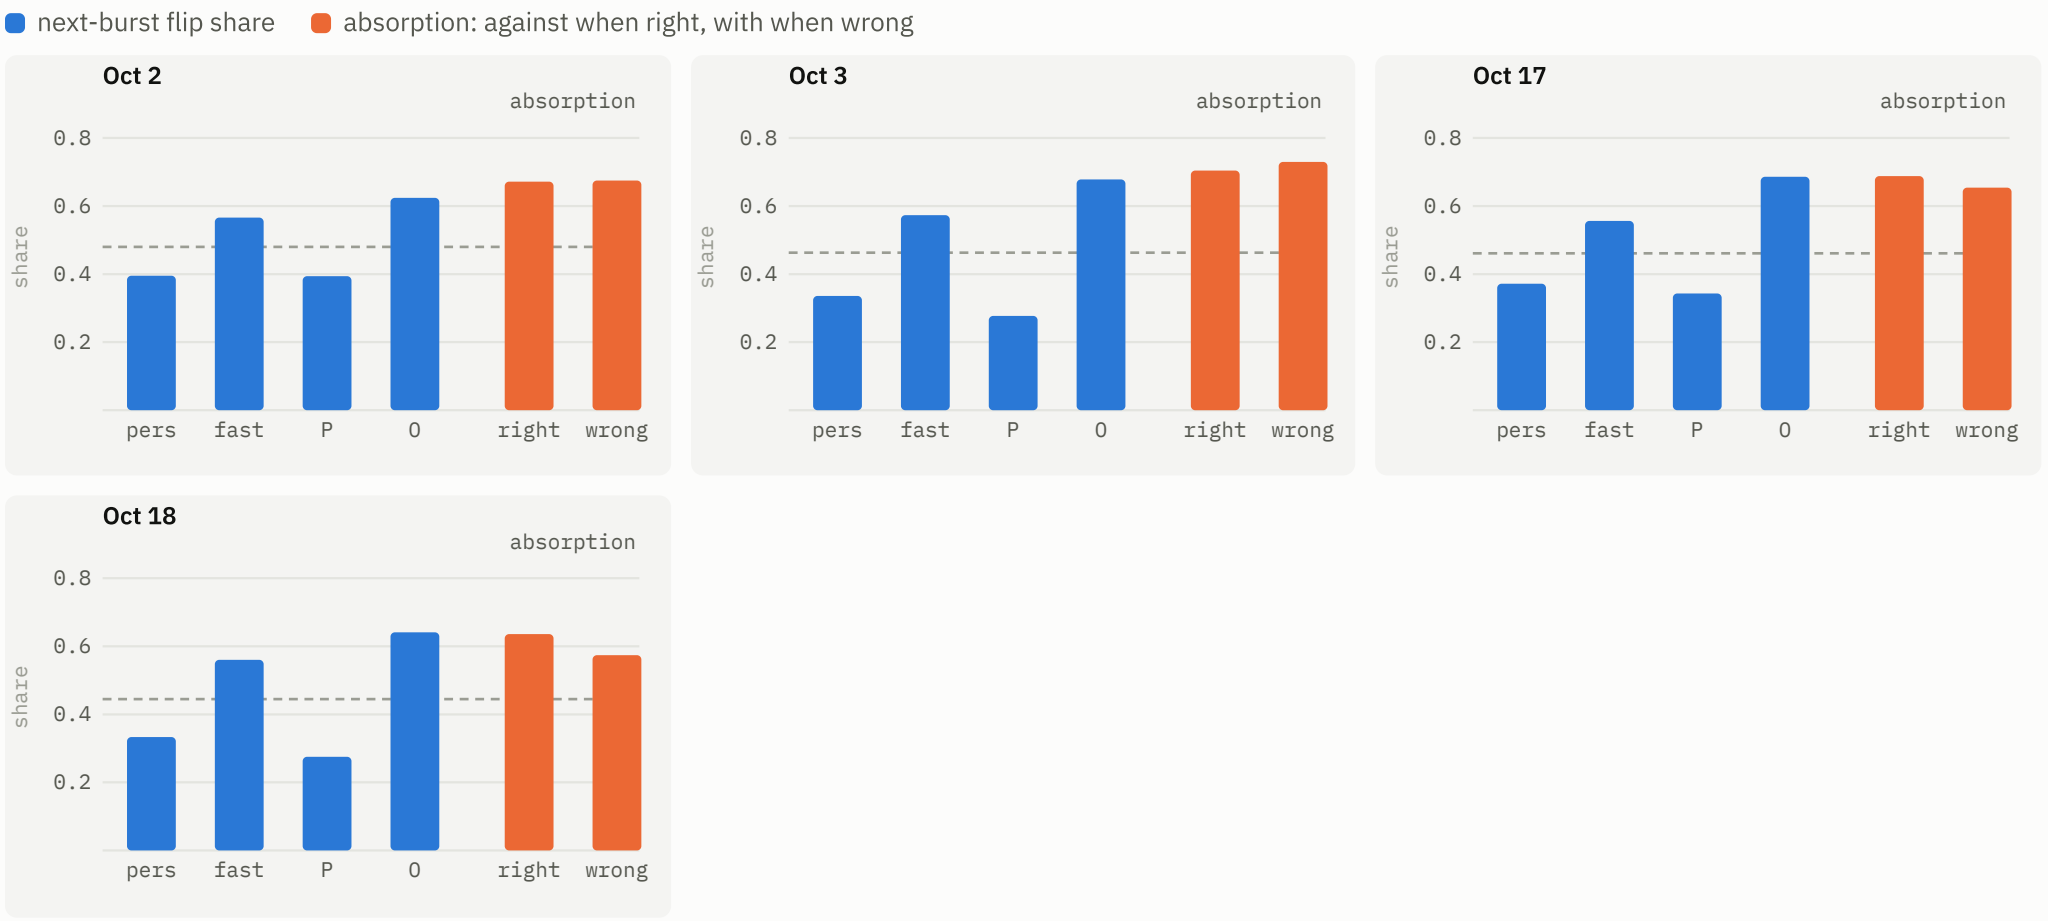

touch aligned to birth · touch opposed to birth · baseline, birth polarity · control, heavier touch side at every active second

Opposed is drawn as with-share of the birth polarity, so it mirrors aligned below 0.5.

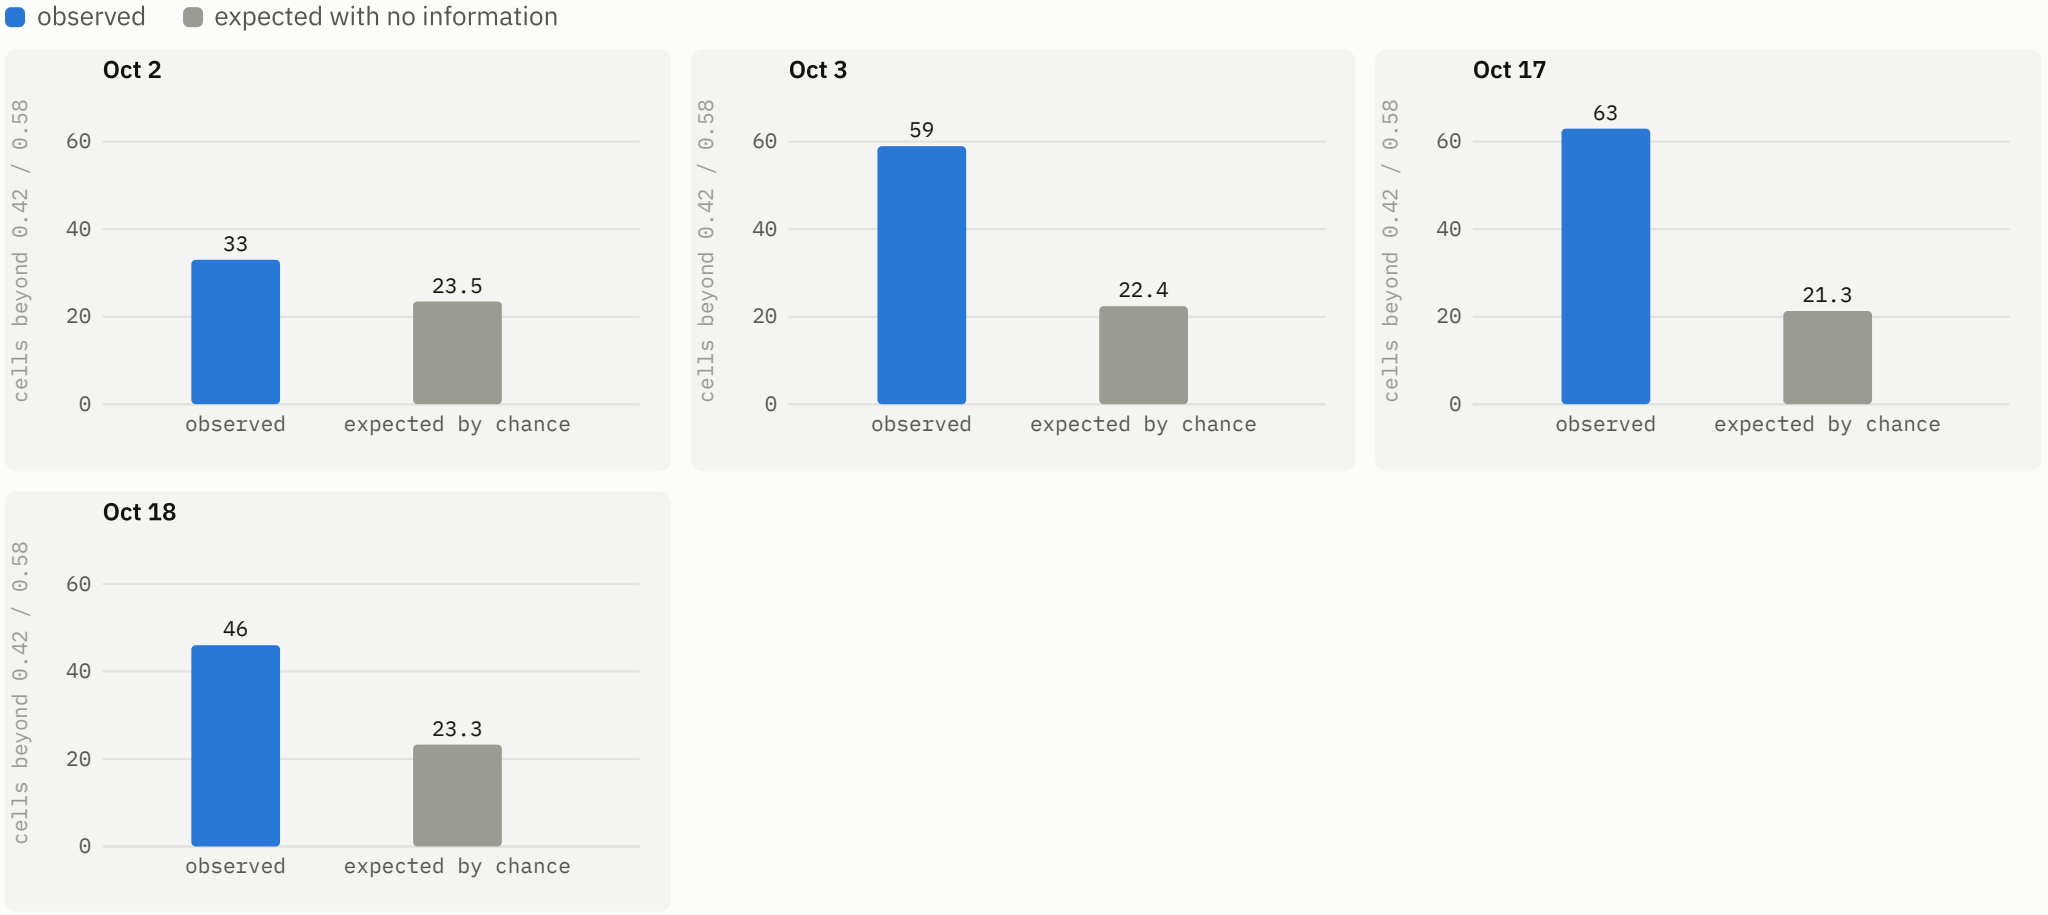

7. The state forecasts the next burst's side, and the expected burst is absorbed

Flip share of the next frozen-detector event (dashed line is the day's base rate). When the forecast is right the price moves against that burst 64 to 70 percent of the time; when it is wrong, with it.

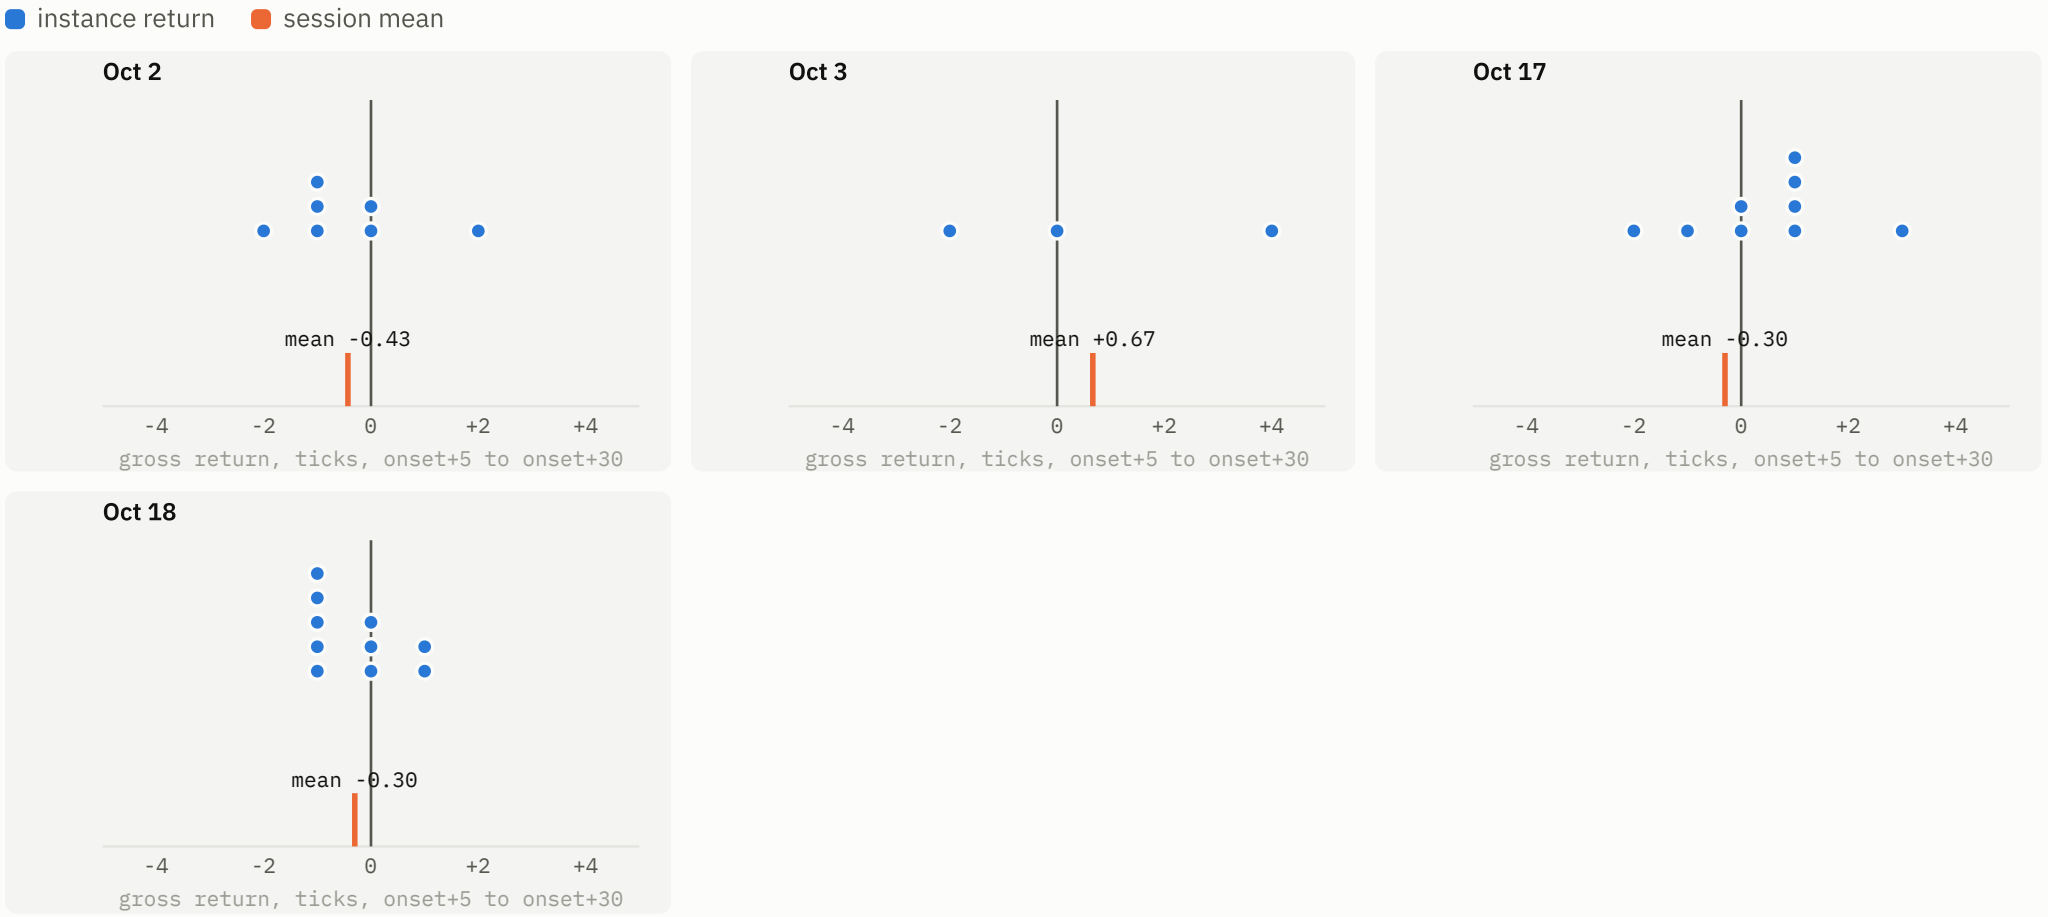

8. Direction cells: structure within each day, none across days

Each session has about twice the extreme direction cells chance predicts, and across sessions the signs agree at chance: 45 of 355 cells on the same side all four days where 44 is expected. The lifts are each day's drift.

9. The frozen SSOS play as written, per session

10 / 10 / 3 / 7 instances on October 2 / 3 / 17 / 18 against 399 to 415 eligible targets. Gross means are negative on three of four sessions; the frozen base averaged plus 0.26 ticks.

Each dot is one play instance; stacked dots share a return. Entry with the current polarity at onset+5 after a confirmed endpoint, exit at onset+30, S,S,O,S predecessors knowable before t0.
